Spin-memory loss (SML) of electrons traversing ferromagnetic-metal/heavy-metal (FM/HM), FM/normal-metal (FM/NM), and HM/NM interfaces is a fundamental phenomenon that must be invoked to explain consistently large numbers of spintronic experiments. However, its strength extracted by fitting experimental data to phenomenological semiclassical theory, which replaces each interface by a fictitious bulk diffusive layer, is poorly understood from a microscopic quantum framework and/or materials properties. Here we describe an ensemble of flowing spin quantum states using spin-density matrix, so that SML is measured like any decoherence process by the decay of its off-diagonal elements or, equivalently, by the reduction of the magnitude of polarization vector. By combining this framework with density functional theory, we examine how all three components of the polarization vector change at Co/Ta, Co/Pt, Co/Cu, Pt/Cu, and Pt/Au interfaces embedded within Cu/FM/HM/Cu vertical heterostructures. In addition, we use *ab initio* Green’s functions to compute spectral functions and spin textures over FM, HM, and NM monolayers around these interfaces which quantify interfacial spin-orbit coupling and explain the microscopic origin of SML in long-standing puzzles, such as why it is nonzero at the Co/Cu interface; why it is very large at the Pt/Cu interface; and why it occurs even in the absence of disorder, intermixing and magnons at the interface.

DOI: 10.1103/PhysRevB.96.220403

Spin-memory loss (SML) of electrons traversing a ferromagnetic metal (FM) and a normal metal (NM) affects numerous spin transport phenomena in current-perpendicular-to-plane (CPP) geometry, such as magnetoresistance [1,2], spin-transfer torque in spin valves [3–5], and Josephson current [6]. In addition, partial absorption of spin current at an interface between ultrathin layers of 3d FM and 5d heavy metal (HM) is of paramount importance for understanding recent spin-orbit torque (SOT) [7–11] and spin-pumping-to-charge conversion [12–15] experiments—neglecting it prevents [14] accurate estimation of the spin Hall angle of HM or interfacial enhancement of Gilbert damping of FM [16]. While bulk spin-orbit coupling (SOC) generated effects are well understood [17], microscopic details of interfacial SOC in FM/HM [18,19], as well as FM/NM or HM/NM, bilayers and its effect on spin transport remain largely uncharted [20]. For example, theoretical studies [21] of SOT often assume simplistic Hamiltonians to describe interfacial SOC and, aside from a handful of studies, [22,23] standard theory [24] of spin pumping by precessing magnetization completely neglects interfacial SOC. In general, SML can be expected due to either interfacial SOC or noncollinear magnetic moments at the interface [25].

Traditionally, SML has been quantified [1,2,6,14] by a phenomenological parameter $\delta$ which determines the probability for an electron to flip its spin direction as it traverses the interface. This parameter is typically extracted [1,2] from the measurement of CPP magnetoresistance in spin valves with multilayer insertions by using the semiclassical Valet-Fert model [26] to express it in terms of the thickness $d$ of a fictitious bulk layer and its spin-diffusion length $\ell_d$.

$$\delta = d/\ell_d.$$  

However, processes at the interface—viewed as a mathematically sharp plane which is, therefore, shorter than any charge or spin dephasing length scale that would make transport semiclassical—require quantum-mechanical description [27,28]. A step in this direction has been undertaken very recently in Ref. [29] by expressing $\delta$ in terms of spin-flip transmission and reflection probabilities at the interface, which were also computed via *ab initio* calculations (such as for the Cu/Pd interface). These probabilities are extracted from the scattering matrix entering the Landauer-Büttiker (LB) description of spin-dependent quantum transport [28,30] which views current of charges or spins as a process where they experience transmission and reflection events as they propagate through the system coherently. The magnetoelectronic circuit approach [20,30] of Ref. [29] introduces tensor conductances that account for both spin precession and loss, but only in the simple case of highly symmetric interfaces it does becomes possible to reduce these conductances to reflection and transmission probabilities and to the well-known parameter $\delta$.

The most general quantum description of SML can be achieved, akin to any decoherence process [31], by examining how transport across the interface reduces the off-diagonal elements of the spin-density matrix [32]

$$\hat{\rho}_{\text{spin}} = \frac{1}{2} \left( 1 + \mathbf{P} \cdot \hat{\mathbf{\sigma}} \right). \quad (1)$$

The $2 \times 2$ Hermitian matrix $\hat{\rho}_{\text{spin}}$ of unit trace—as the most general description of spin-$\frac{1}{2}$ states [32], which can also be associated with electronic current viewed as an ensemble of “flowing” spin quantum states [33]—is specified by the three real parameters. Therefore, it can equivalently be determined by the polarization vector $\mathbf{P} = \text{Tr}[\hat{\rho}_{\text{spin}} \hat{\mathbf{\sigma}}]$, where $\hat{\mathbf{\sigma}} = (\hat{\sigma}_x, \hat{\sigma}_y, \hat{\sigma}_z)$ is the vector of the Pauli matrices. Pure spin quantum states, carried by 100% spin-polarized current, are characterized by $|\mathbf{P}| = 1$; incoherent spin states, carried by conventional unpolarized charge current, are characterized by $|\mathbf{P}| = 0$.
FIG. 1. Schematic view of a vertical heterostructure for quantum transport calculations of SML, where FM/HM bilayer is sandwiched between two semi-infinite Cu(111) NM leads. Small bias voltage \( V_s \) applied between the leads injects unpolarized charge current from the left Cu lead along the \( z \) axis in the linear-response regime. We consider FM=Co(0001) and HM=Ta(001),Pt(111). The FM layer thickness is fixed at 4 monolayers (MLs), or it can be semi-infinite (by removing the left Cu lead), while HM layer thickness is varied from 0 to 5 MLs. We calculate spectral functions and spin textures on planes 1 and 2 passing through MLs of FM and HM in direct contact at the FM/HM interface, respectively, or on planes 3 and 4 passing through MLs of HM and Cu around the HM/Cu interface, respectively. The device is assumed to be infinite in the transverse direction, so that the depicted supercell is periodically repeated within the \( xy \) plane.

\[ |P| = 0; \text{ and partially coherent \[33\] spin states, carried by partially spin-polarized charge current, are characterized by } 0 < |P| < 1. \]

In this Rapid Communication, we combine calculation of \( \hat{\rho}_{\text{spin}} \) in terms of nonequilibrium Green’s functions \[34\] whose input Hamiltonian is obtained from density functional theory (DFT) theory applied to vertical heterostructures illustrated in Fig. 1 where a bilayer composed of FM=Co(0001) and HM=Ta(001),Pt(111) is attached to one or two Cu(111) semi-infinite leads. The magnetization \( m_{\text{Cu}} \) of the Co layer, which defines direction of \( \hat{P}_{\text{FM}} \), is aligned either parallel (i.e., along the \( x \) axis in Fig. 1) or perpendicular (i.e., along the \( z \) axis in Fig. 1) to the interface. The semi-infinite leads are taken into account through the corresponding \( ab \) initio computed self-energies \[35\], where unpolarized charge current is injected through the left Cu lead and spin-polarized charge current is drained through the right Cu lead.

The setup in Fig. 1 is inspired by CPP magnetoresistance-based experimental measurements \[1,2\] of \( \delta \) where a FM/NM bilayer, whose layers are thinner than \( \ell_{\text{id}} \), is inserted into the Cu layer in between two FM electrodes of a spin valve, except that in our computational scheme we do not need additional right and left FM leads. Our realistic setup also evades the need for artificial \[29\] introduction of two regions—with and without SOC—within the same HM semi-infinite layer due to the fact that spin current or \( \hat{\rho}_{\text{spin}} \) cannot be uniquely defined along a semi-infinite lead with SOC \[36\].

For clean junctions in Fig. 1 in the ballistic transport regime, we compute \( \hat{\rho}_{\text{out}}^{\text{NM}} \) for current outflowing into the right Cu lead as a function of the thickness \( d_{\text{HM}} \) of the HM interlayer varied from 0 to 5 MLs. Thus, the parameter \[14\]

\[ \zeta = \frac{|\hat{P}_{\text{out}}^{\text{NM}}|}{|\hat{P}_{\text{FM}}^{\text{out}}(d_{\text{HM}} = 1 \text{ ML})|} \]  

quantifies SML at the FM/HM interfaces, where \( |\hat{P}_{\text{FM}}^{\text{out}}| \) is polarization generated by an infinitely thick FM layer and \( |\hat{P}_{\text{out}}^{\text{NM}}(d_{\text{HM}} = 1 \text{ ML})| \) is the polarization of current in NM lead after insertion of 1 ML of HM. In the case of FM layers of finite thickness, we use \( \hat{P}_{\text{FM}}^{\text{out}} = \hat{P}_{\text{out}}^{\text{NM}}(d_{\text{HM}} = 0 \text{ ML}) \).

Since \( \zeta \) measures the fraction of spin current absorbed at the interface, its values in Table I can be utilized as an \( ab \) initio boundary condition that is otherwise often introduced \[14,20,23,37\] as a phenomenological parameter \( 0 \leq \zeta \leq 1 \). Note also that \( \zeta = |\cosh(\delta) + r \sinh(\delta)|^{-1} \) can be expressed in terms of measured \( \delta \) and spin resistances of different layers which specify parameter \( r \) defined in Ref. \[14\]. Since \( \zeta \) can be affected by both FM/HM and HM/NM interfaces in the setup in Fig. 1, as also encountered in realistic junctions, we investigate the effect of the second HM/NM interface by comparing NM=Cu and NM=Au cases.

By considering current outflowing into the right lead of a two-terminal junction as an ensemble (albeit nonunique \[32\]) of spin quantum states, the expression for \( \hat{\rho}_{\text{spin}}^{\text{out}} \), was derived in Ref. \[33\] in terms of the transmission submatrix \( t \) of the full scattering matrix as the central quantity in the LB approach to quantum transport \[28,30\]. For the general case of partially spin-polarized current injected from the left lead, whose spins are described by \( \hat{\rho}_{\text{spin}}^{\text{in}} = p_\uparrow |\uparrow\rangle \langle \uparrow| + p_\downarrow |\downarrow\rangle \langle \downarrow| \), \( \hat{\rho}_{\text{spin}}^{\text{out}} \) is given by \[33\]

\[
\hat{\rho}_{\text{spin}}^{\text{out}} = \frac{e^2/\hbar}{p_\uparrow (G^{\uparrow\uparrow} + G^{\uparrow\downarrow}) + p_\downarrow (G^{\downarrow\uparrow} + G^{\downarrow\downarrow})} \sum_{n',n=1} \left( p_\uparrow t_{\nu,n',\uparrow} t_{\nu,n',\uparrow}^\dagger + p_\downarrow t_{\nu,n',\downarrow} t_{\nu,n',\downarrow}^\dagger \right) \left( p_\uparrow t_{\nu,n',\uparrow} t_{\nu,n',\uparrow}^\dagger + p_\downarrow t_{\nu,n',\downarrow} t_{\nu,n',\downarrow}^\dagger \right) \left( p_\uparrow t_{\nu,n',\uparrow} t_{\nu,n',\uparrow}^\dagger + p_\downarrow t_{\nu,n',\downarrow} t_{\nu,n',\downarrow}^\dagger \right).
\]  

(3)

Here \( t_{\nu,n',\sigma'} \) are complex numbers determining probability amplitude for a spin-\( \sigma' \) electron incoming from the left lead in the orbital state \( |n\rangle \) to appear as a spin-\( \sigma \) electron in the orbital channel \( |n'\rangle \) in the right lead. The zero-temperature
spin-resolved conductances $G^{\sigma \sigma'}$ are given by the LB formula, $G^{\sigma \sigma'} = \frac{\pi e^2}{h} \sum_{\sigma, n, n'} |t_{\sigma n, n' \sigma'}|^2$. Using 100% spin-polarized current injection, $p_1 = 1.0$ and $p_2 = 0$, Eq. (3) can be used to study SML at NM/HM interfaces within NM/HM/NM junctions [29]. For unpolarized current injection, $p_1 = p_1 = 0.5$, where current can be subsequently polarized by explicitly introducing a FM layer as in Fig. 1, the polarization vector can be equivalently calculated [38] using $P_\sigma = \text{Tr}(\hat{\sigma}_\sigma \mathbf{t}) / \text{Tr}(\mathbf{t})$. We obtain the transmission matrix, $\mathbf{t} = \sqrt{-2\text{Im} \Sigma^{L}_k(E) \cdot \mathbf{G}_k(E)} \cdot \sqrt{-2\text{Im} \Sigma^{R}_k(E)}$, using the retarded Green’s function (GF)

$$G_k(E) = \left[ E - \mathbf{H}^{\text{DFT}}_{k_{\parallel}} - \Sigma^L_k(E) - \Sigma^R_k(E) \right]^{-1},$$

where $\mathbf{H}^{\text{DFT}}_{k_{\parallel}}$ is the DFT Hamiltonian computed for the active plane-wave basis set is chosen as 600 eV, while k points were sampled at $9 \times 9$ surface mesh. The atomic coordinates are allowed to relax until the forces on each atom are less than 0.01 eV/Å, while keeping the interlayer distances fixed. Ab initio quantum transport calculations are performed using the ATK package [43] where we use the PBE XC functional, norm-conserving pseudopotentials for describing electron-core interactions, and SG15 (medium) type local orbital basis set [44]. The energy mesh cutoff for the real-space grid is chosen as 76.0 hartree. Transmission matrices are obtained by integrating over 251 × 251 k-point mesh.

The abrupt change of $\mathbf{P}$ at different FM/HM interfaces can be read off from the abscissa of Fig. 2 as we change from 0 or 1 ML of HM. The corresponding values of parameter $\zeta$ defined in Eq. (2) are given in Table I. Values at 2–5 ML of HM can also be viewed as the change of $\mathbf{P}$ along the HM layer of 5 ML thickness. An infinitely long Co layer generates $|\mathbf{P}| \approx 0.26$, which is denoted by a dashed horizontal line in Fig. 2(c). Upon attaching Cu to the Co layer, and in the absence of any HM interlayer in between them, $|\mathbf{P}|$ reduces to $\approx 0.20$ in Fig. 2(a) for the Cu/Co(4ML)/Cu junction or to $|\mathbf{P}| \approx 0.18$ in Figs. 2(c) and 2(d) for the semi-infinite-Co/semi-infinite-Cu junction. At first sight, it might look surprising that the finite thickness Co(4 ML) layer generates larger spin polarization of charge current than the semi-infinite Co layer. However, we note that surfaces of Co [see Figs. 4(a)–4(d) in Ref. [45]] and Cu [see Fig. 5(b) in Ref. [46]] can host Rashba SOC enabled by inversion symmetry breaking where an electrostatic potential gradient can be created by the charge distribution at the metal/vacuum interface to confine wave functions into a spin-split quasi-two-dimensional electron gas [47].

Since the Cu/Co(4 ML)/Cu junction is inversion symmetric, we expect zero SOC at its interfaces [7], while nonzero SOC should appear at the single interface of the Co/Cu junction. This is confirmed by plotting spectral function $A(E; k_x, k_y, z)$ at ML of Co on the left side of the interface in Fig. 3(i), as well as the corresponding spin texture along constant energy contours of the spectral function at $E = E_F = 0$ in Fig. 3(j). Even larger spin texture is obtained on ML of Cu on the right side of the Co/Cu interface which is, therefore, most responsible for SML at the Co/Cu interface, thus resolving the controversy [2] of zero vs nonzero measured values for $\delta$. Following Ref. [45], we obtain the spectral function at an arbitrary plane at position $z$ within the heterostructure in Fig. 1 from the retarded GF in Eq. (4),

$$A(E; k_x, k_y, z) = \frac{1}{\pi} \text{Im} \left[ G_k(E; z, z) \right].$$
and (d) plot constant energy contours of \( A \) out-of-plane \( \text{Sz} \)
Rashba Hamiltonian \[48\] often employed in calculations of
interface are quite different from those of the ferromagnetic
while it is caused mostly by the Pt ML in the latter case. We
SML is caused by both Co and Ta MLs in the former case,
and around the Co/Pt interface in Figs. 2(e)–2(h) reveals that
and spin textures around the Co/Ta interface in Figs. 2(a)–2(d)
SOT \[21\] or spin pumping in the presence of interfacial SOC
within the Co/Pt(4 ML)/Cu junction. The units for
function.

The parameter \( \zeta \) listed in Table 1 is much smaller for
the Co/Pt interface studied in Fig. 2(d) than for the Co/Ta
interface studied in Fig. 2(a) for the same orientation of
magnetization, \( \mathbf{m}_{\text{Co}} \parallel \hat{z} \). Inspection of the spectral functions
and spin textures around the Co/Ta interface in Figs. 2(a)–2(d)
and around the Co/Pt interface in Figs. 2(e)–2(h) reveals that
SML is caused by both Co and Ta MLs in the former case,
while it is caused mostly by the Pt ML in the latter case. We
emphasize that spectral functions and spin textures at the Co/Pt
interface are quite different from those of the ferromagnetic
Rashba Hamiltonian \[48\] often employed in calculations of
SOT \[21\] or spin pumping in the presence of interfacial SOC
\[22,23,49\].

Figure 2 also reveals that while 1 ML of HM always acts
as a “spin sink,” 2 MLs can also act as a “spin source” \[20\] by
repolarizing charge current flowing from the first to the second
ML of HM. Nevertheless, such “repolarization” is eventually
lost sufficiently further away from the FM/HM interface. In the
presence of scattering from disorder and/or phonons excited
at finite temperature \[50\] within the HM layer, the decay of
P away from the interface would be monotone decreasing
exponential function. On the other hand, it has been shown \[16\]
that SML (i.e., the value of \( \delta \) or \( \zeta \) parameters) can be insensitive
to interfacial disorder, despite its strong effect on interface
resistances, thereby emphasizing the need to understand SML
in a clean system in the focus of our study.

Since SML is particularly strong in the Co/Pt/Cu junction
in Fig. 2(d), with \( \zeta \approx 0.04 \) signifying almost complete
absorption of spin current by the interface, we also investigate
the Co/Pt/Au junction in Fig. 2(d) to find much larger \( \zeta \approx 0.29 \).
Thus, this difference explains the experimentally observed \[1\]

where the diagonal matrix elements \( G_k (E; z, \zeta) \) are computed
by transforming the retarded GF from local orbital to a real-
space representation. The spin textures within the constant
energy contours are computed from the spin-resolved spectral
function.

**FIG. 3.** Spectral function \( A(E; k_x, k_y, z \in \{1, 2\}) \) in Eq. (5) plotted along the high-symmetry \( k \) path, \( X-\Gamma-Y \) at (a) plane 1 in Fig. 1 passing
through a ML of Co; and (c) plane 2 in Fig. 1 passing through a ML of Ta within the Cu/Co/Ta(4 ML)/Cu junction with \( \mathbf{m}_{\text{Co}} \parallel \hat{z} \).
Panels (b) and (d) plot constant energy contours of \( A(E - E^0 = 0; k_x, k_y) \) on planes 1 and 2, respectively, and the corresponding spin textures where the
out-of-plane \( S_z \) component of spin is indicated in color (red for positive and blue for negative). Panels (e)–(h) show the same information on
planes 1 and 2 passing through the ML of Co and the ML of Pt, respectively, within the Co/Pt(4 ML)/Cu junction. Panels (i)–(l) show the same
information on planes 1 and 2 passing through the ML of Co and the ML of Cu, respectively, within the semi-infinite-Co/semi-infinite-Cu
junction. Panels (m)–(p) show the same information on planes 3 and 4 in Fig. 1 passing through the ML of Pt and the ML of Cu, respectively,
within the Co/Pt(4 ML)/Cu junction. The units for \( k_x \) and \( k_y \) are \( 2\pi/a \) and \( 2\pi/b \) where \( a \) and \( b \) are the lattice constants along the \( x \) and \( y \) axis, respectively. The horizontal dashed black line in the spectral function panels denotes the position of the Fermi energy \( E_F \).
large SML at the Pt/Cu interface, which is often [1,14] naively attributed to interfacial diffusion and disorder. Instead, by plotting the spectral functions and spin textures in Figs. 2(m)–2(p) at the MLs of Pt and Cu, where spin textures on both sides of the Pt/Cu interface are the largest among the cases in Fig. 2, we demonstrate that large SML occurs even at perfect Pt/Cu interface because of strong interfacial SOC.

In the presence of interfacial SOC electrons trade angular momentum with the atomic lattice that can lead to changes of all three [20] components of $\mathbf{P}$. Figure 2(b) shows that for injected spins polarized parallel to the interface—i.e., $P_x \neq 0$ while the other two components of the incoming polarization vector are zero due to $\mathbf{n}_{\text{Co}} \parallel \hat{x}$—SML reduces the magnitude of $P_x$ while also generating non-negligible $P_z$ out of the plane. Interestingly, very recent experiments [51] on lateral FM1/NM/FM2 trilayers with charge current injected parallel to the plane, where magnetization of FM1 layer is in-plane and fixed while the magnetization of FM2 layer is out-of-plane and free, have observed out-of-plane spin current with nonzero $P_z$ as advantageous for switching magnetization of FM2 layer via torque in the absence of any externally applied magnetic field. This is fully compatible with Fig. 2(b), once we take into account that spin current impinging perpendicularly onto FM1/NM interface originates from the anomalous Hall effect [48] in the FM1 layer and carries only in-plane polarized spins.

Finally, since change of the polarization vector along HM layers of different thicknesses in Fig. 2, as well as the peculiar thickness dependence of SOT observed in Co/Ta bilayers [9], can be affected by the magnetic proximity effect [19,52]—where FM induces nonzero magnetic moments within MLs of HM sufficiently close to the interface—we plot in Fig. 4 the spatial profile of average magnetic moment per atom across junctions studied in Fig. 2. The characteristic magnetization decay length within Pt in Fig. 4(c) is longer than in Ta in Figs. 4(a) and 4(b), where 1 ML of Ta is also capable of surprisingly large suppression of magnetic moments on the FM side for both finite and infinite thickness of the Co layer.

We thank K. D. Belashchenko, A. A. Kovalev, K.-J. Lee, and Z. Yuan for insightful discussions. This work was supported by DOE Grant No. DE-SC0016380. The supercomputing time was provided by XSEDE, which is supported by NSF Grant No. ACI-1053575.
